

Online Supplementary Material for
Seasonality, the Latitudinal Gradient of Diversity, and Eocene Insects

S. Bruce Archibald, William H. Bossert, David. R. Greenwood, and Brian D. Farrell

Online material includes:

- Analysis of ichneumon wasp specimens

 - Online Figure 1

 - Online Table 1

- Analysis of *Plecia* specimens

 - Online Figure 2

- Comparisons of climatic estimation methods

 - Online Table 2

- Online Table 3: General compositions of McAbee, Harvard Forest and La Selva samples

- Online literature cited

- Online Table 4: Specimen / species compositions of samples

Analysis of ichneumon Wasp Specimens

Size was not used in determination of ichneumonid wings to species due to its range within individuals of a species and sexual dimorphism, except in the extreme case of specimen 1988. Wings were grouped into six major groups (A-F) based on the shape of the “areolet”, the first Rs cell, a small cell in the centre of the forewing (online fig. 1). They were then categorized within each of these groups by combinations of three wing characters, and then further separated by comparisons of ratios of character measurements between the fossil specimens and in known, extant species.

Separation to groups

Abscissa numbers refer to those defined in online fig. 1D.

Group A: areolet triangular, or sub-triangular; abscissa 1 meets abscissa 3 (no or very short abscissa 2); abscissa 3 meets abscissa 5 (no abscissa 4);

Group B: areolet as in Group A, but open, i.e., abscissa 3 space empty or very weak;

Group C: areolet sub-triangular; but abscissa 4 present (Group A: absent), short relative to length of abscissa 3; abscissa 4 parallel or subparallel with abscissa 1; abscissa 1 meets abscissa 3 (no or very short abscissa 2);

Group D: as in Group C, but areolet open, i.e., abscissa 3 space empty or very weak;

Group E: areolet diamond-shaped: four-sided or slightly five-sided (if a short length of abscissa 2 present between abscissa 1 and abscissa 3), no side less than half length of other (other than brief length of abscissa 2, if present, as above);

Group F: areolet distinctly pentagonal: all five abscissae distinctly present (two abutting sides may be aligned).

Within these “areolet groups”, specimens were separated to subgroups by differing combinations of states of the following characters.

Character 1: 2m-cu: A) distinctly curved or B) rather straight;

Character 2: crossvein cu-a: joins Cu: A) at, or B) distad branching of M+Cu to M and Cu;

Character 3: cu-a joins A: A) at a distinct angle, or B) perpendicular or closely so to A.

Separation to species

Within subgroups, specimens that shared the same states of characters 1-3 were evaluated further with ratios of measurements of wing characters. Twelve measurements (A-L) of forewing characters were taken from camera lucida drawings of each fossil. Ratios of pairs of the measurements were used to control for intra-specific size differences (individual and by sexual dimorphism). These were compared with inter- and intra-specific variation in known species, taken from photographs of forewings of 96 specimens of 9 extant species (pinned specimens, MCZ) in three genera of three subfamilies. These were: *Pterocormus annulatorius* (n = 9), *P. bucculentus* (n = 4), *P. centrator* (n = 10); *Compsocryptus texensis* (n = 7), *C. resolutus* (n = 6), *C. melanostigmus* (n = 18); *Coccygomimus semirufus* (n = 8), *C. sumichrasti* (n = 21), *C. tomyris* (n = 23).

Within extant species, the average value of each ratio within that species was taken, and its standard deviation within the species was determined. Within each species, no specimens were separated by more than two standard deviations, and all individuals species differed by more than two standard deviations between them. For a given ratio, the coefficient of variation, the ratio of standard deviation divided by the mean was constant within and differed consistently between species over all species examined.

Three ratios, together, separated all extant species, and were compared in the fossil specimens: L/C, D/C, and J/K. These ratios in part describe the shapes of cells 2R1 and 2M.

Specimens were grouped for a given ratio-character if they did not differ by more than three times the coefficient of variation for that ratio times their mean value, and were considered to have a species-level difference for that character if the difference between their values was greater than that amount. All those specimens were included in the same species that are within three standard deviations of any member of the species group, i.e., two may differ by more, but a third that is intermediate and differs from neither by more than three the set amount bound those two together.

Online Figure 1: Forewing of *Pterocormus centrator* with characters of Ichneumonidae mentioned in the text. (A), (B) measurements taken. (C) cells Ar (areolet), 2M, and 2R1 in *italics*; veins M+Cu, Cu and A; crossveins cu-a and 2m-cu. (D) veins and crossveins surrounding the areolet; circled numbers, see text. (A)–(C) to scale, 5 mm; (D) to scale, 1 mm.

Analysis of *Plecia* Specimens

March flies, species of the genus *Plecia* (Diptera: Bibionidae: Pleciinae), are the most common insects at most Okanagan Highlands localities, and comprise about a quarter of this fossil assemblage. Handlirsch (1910) defined twenty species in the British Columbia Eocene, a number Cockerell (1925: p. 12) called “scandalous”. Rice (1959) revised these, added another two species, and placed two in *Penthetria*, the sister taxon to *Plecia*, which has very similar wings.

Unfortunately, none of these authors provided diagnoses for these species, as was the custom then. Intraspecific variation in wing morphology as illustrated by Rice appears larger than differences between many species pairs. Although they are common fossils, no species determinations for Okanagan Highlands *Plecia* (or *Penthetria*) specimens have been subsequently published. Wilson (1977: p. 1146) noted that assignment of these bibionid specimens to species is “extremely difficult”, and suggested that further revision of the Okanagan Highlands Bibionidae is necessary.

The approach taken here was similar to that taken for the Ichneumonidae. Twenty-three characters were measured on each wing (A-W, online fig. 2) of 129 well-preserved specimens out of 335 total. To control for size differences in intra-specific variation and sexual dimorphism, only ratios of these were used, yielding $23 \times 22 / 2 = 253$ possible distinct ratios. Unfortunately, many fossil specimens are incomplete in some portion, precluding some measurements.

To establish intra- and inter-specific variation in these ratios to compare among the fossils, 53 specimens of 5 extant species of *Plecia* were examined and measured (males and females): *P. nearctica* (n = 20), *P. americana* (n = 4), *P. ephippium* (n = 8), *P. plagiata* (n = 13), and *P. collaris* (n = 8); and 18 further specimens of the pleciine *Penthetria heteroptera*.

To establish if there was sexual dimorphism in the ratios themselves, which would hinder their use in species identification, the sum of squares of a ratio about its mean was partitioned into the between sex and within sex components, as in an analysis of variance. A ratio was rejected if the between sex component was more than 20% of the total.

Of the 253 possible measurement ratios, only 69 were sufficiently non-dimorphic to appear useful. Of these 69, many were highly correlated; hence, using all of them added nothing to our discrimination that a much smaller subset could achieve. A set of ratios were identified, which were not sexually dimorphic, which were not significantly correlated, which had a relatively small variance within an extant species, yet which had a much larger variance over the fossil specimens. They are: A/W, E/U, C/P, K/M, B/J, N/Q, T/W, R/U, I/O, Q/V, and A/F.

These ratios are highly diagnostic for the modern species. Linear Discriminant analysis using them split individual pairs of the 5 extant species perfectly, with Mahalanobis D^2 values all in excess of 18. This is not helpful with regards to the fossils specimens, as the goal is not to assign them to modern species. It does suggest, however, that the ratios could be useful, with the caveat that only a subset are available in many due to partial preservation. No small subset of these ten ratios (two or three) reliably separates all of the extant species.

A Principal Components Analysis was done on the ten ratios over the extant species sample. The first two principal components explained about 90% of the total variance over the extant species. Unfortunately, projecting the data matrix for the extant species on these two main components did not separate the species.

Returning to the full set of 69 non-dimorphic ratios, variance of individual ratios between species was examined. Between each pair of extant species, with one notable exception, there was no overlap in ratio values for at least five of the ratios and at least one ratio in which the mean difference between the species was at least 0.33 times the average mean over the two species. This compares to the within species coefficient of variation, in which the standard deviation in any ratio was never more than about 17% of the mean, usually less than 10%. The exception to this result is the comparison of *P. nearctica* and *P. collaris*, which had overlap in all 69 of the non-dimorphic ratios. Despite this one failure, it seemed that a possible rule for grouping specimens into species was to pair specimens that did not differ in any one ratio by more than 30% of the mean value for that ratio in the two species. When this rule is applied to the aggregate 56 specimens of the five extant species, only $32/56 = .57\%$ were assigned to their known species group correctly. A major error was assigning five of the *P. collaris* to the *P. nearctica* group. The number of specimens assigned to a single specimen group was $18/56$, yielding a total of 22 “species” groups instead of the known 5 species. This increased the logarithmic Shannon species diversity index from 1.49 to 2.17, an error that seems intolerable. This amounts to an increase in the number of “effective” species taking relative abundance into consideration from 4.44 to 8.76. When this rule was applied to the fossil *Plecia* specimens 128 of the unknown specimens were assigned to 1 species and 1 specimen to a second species.

A rather arbitrary examination was done on the effect of reducing the difference required in any one ratio for separating a pair of specimens into two species, while adding a requirement that the average difference between the specimens over all of the ratios for which they have data in common. When two specimens were considered conspecific that do not differ by more than 34% of the mean of any one ratio, but split when the average relative difference (difference divided by the mean for the two specimens) over all ratios in common, the Shannon’s species diversity index was 1.49, exactly the known value. However, about 40% of the specimens were categorized incorrectly as to known species. Applying this mixed rule to the fossil specimens changed nothing. The result was two species with nearly all of the specimens in one species. Of course, this could be the correct categorization of the fossils, but the method for achieving it is very ad hoc, and cannot be accepted.

By the inability to obtain reliable species determinations for these fossil *Plecia* on the basis of these wing measurements, they were excluded.

Online Figure 2: *Plecia nearctica* wing, female. (A) habitus, (B) measurements taken on *Plecia* and *Penthetria* specimens; both to scale, 2 mm.

Comparison of Climatic Estimation Methods
Online Table 2

COMPARISONS OF WEATHER STATION DATA AND PALEOCLIMATE EVALUATION METHODS.

site	N	LMP	MAT(obs)	MAT(LMA)	error	N	MAT(NLR)	error

HF	33	-7.4	-1.4	±9.1
Mc	35	—	5.8	±2.0

site	N	MAP(obs)	MAP(NLR)	error
LS	29	396	126	±34
HF	33	107	111	±45
Mc	35	—	108	±36

NOTE. —Abbreviations: mean annual temperature (MAT), coldest month mean temperature (CMMT) and mean annual precipitation (MAP), observed weather station data (obs) and nearest living relative (NLR) and leaf margin analysis (LMA). Data from La Selva (LS), Costa Rica; Harvard Forest (HF), Massachusetts, USA; Eocene McAbee (Mc), British Columbia, Canada. N is the number of leaves (LMA) or taxa (NLR) used; LMP is the percent entire margined (non-toothed) woody dicot leaves. MAT and CMMT in °C and MAP in cm/year.

For comparative value, the paleoclimatic estimation methods employed to evaluate McAbee climate (LMA and NLR) were done for Harvard Forest and La Selva, and results were compared with observed on-site weather station data. Harvard Forest LMA was calculated based on LMP data from Royer et al. (Royer et al. 2005), and La Selva on a new leaf collection. NLR was based on Harvard Forest online taxon lists (Harvard Forest 2006), and La Selva on determinations of the leaf collection by Orlando Vargas and Jose Gonzalez.

The LMA MAT for Harvard Forest, Massachusetts was accurate, with the mean value within 0.4° C of the observed weather station value. The mean value of the NLR estimate of MAT for Harvard Forest was about two degrees high, but with error values accurately reflected observed MAT. CMMT (NLR only) gave the Harvard Forest observed value, but only within the large error values. At La Selva, however, CMMT was underestimated, slightly inflating its prediction of seasonality there. MAP by NLR (only) gave a quite accurate prediction of the observed annual precipitation at Harvard Forest, but was less successful at La Selva, where it was underestimated by more than a third. CMMT and MAP are difficult to estimate using either proxy, with large errors and under-estimation a common outcome when calibrated using modern sites. The lower than

observed MAT and CMMT NLR estimates for La Selva are due in part to the inclusion in the calculation of genera of Lauraceae and some other taxa (e.g., Aquifoliaceae, Clethraceae, and Symplocaceae) that are typical of higher elevation forests. The presence of tree taxa in the La Selva forests that are typical of cooler upland forests is thought to be due to the ever-wet and cloudy character of the climate (Gentry 1990; Hammel 1990). The inconsistencies reported here between observed and estimated MAP are similar to those reported in other studies, and may reflect many plant taxa responding to precipitation as a threshold or stepped response, rather than as a linear response (Greenwood 2001; Burnham et al. 2005).
